

## 2.16

- Partitioning the mesh into two equal parts of  $p/2$  processors each would leave  $\sqrt{p}$  communication links between the partitions. The bisection width is  $\sqrt{p}$ .
- The network has a bus underlying infrastructure so by configuring the network appropriately, the diameter is  $O(1)$ . That can be debated because of the need for re-configuration and the fact that other parts of the network may be cut, leaving more than 1 link for processors to communicate.
- There are  $p$  processors, 6 switching nodes per processor, so  $6p$  switching nodes in total.
- Number of communication links is  $2(p-\sqrt{p})$ . It would be  $2p$  with wrap-around so we remove  $2\sqrt{p}$  for the wrap-around links.
- Advantages and disadvantages: We discussed them during the exercise session.

## 2.17

- Partitioning the mesh into two equal parts of  $p/2$  processors each would leave at least  $\sqrt{p}$  links between the partitions. This is similar to the ordinary 2-D mesh. The bisection width is  $\sqrt{p}$ .
- For the diameter we consider the processors at the two extremities of the mesh. As for the 2-D mesh we traverse a full row and a full column, i.e., two binary trees here. The binary tree has height  $\log\sqrt{p}$ , we go up and down the tree for each of the dimension:  $2\log\sqrt{p} + 2\log\sqrt{p} = 2\log p$ .
- Number of switches: Each row and column has  $\sqrt{p}-1$  switches. There are  $\sqrt{p}$  rows and  $\sqrt{p}$  columns. Total is  $2\sqrt{p}(\sqrt{p}-1)$  switches.
